(February 7, 2008)

It has been argued that a black hole horizon can support the long range fields of a Nielsen-Olesen string, and that one can think of such a vortex as black hole “hair”. We show that the fields inside the vortex are completely expelled from a charged black hole in the extreme limit (but not in the near extreme limit). This would seem to imply that a vortex cannot be attached to an extreme black hole. Furthermore, we provide evidence that it is energetically unfavourable for a thin vortex to interact with a large extreme black hole. This dispels the notion that a black hole can support ‘long’ Abelian Higgs hair in the extreme limit. We discuss the implications for strings that end at black holes, as in processes where a string snaps by nucleating black holes.

04.40.-b, 11.27+d, 04.70.-s, 98.80Cq

Black hole ‘hair’ is defined to be any field(s) associated with a stationary black hole configuration which can be detected by asymptotic observers but which cannot be identified with electromagnetic or gravitational degrees of freedom. A number of results have been proven ([1]) which imply that black holes ‘have no hair’. These results led people to believe that a black hole horizon can only support charges associated with long range gauge fields. However, this prejudice was to some extent discredited when Bartnik and McKinnon [2] discovered a solution of the Einstein- Yang-Mills equations which supported Yang-Mills fields which can be detected by asymptotic observers; one therefore says that these black holes are *coloured*. However, these exotic solutions do not impugn the original no hair results since all such solutions are known to be unstable (see e.g. [3]). Since the original no hair theorems assumed a stationary picture they simply do not apply to coloured holes. On the other hand, coloured holes do still exist and so they are said to ‘evade’ the usual no hair results. These results teach us that we have to tread carefully when we start talking about black hole hair.

With this in mind, we analyze the extent to which hair is present in situations involving topological defects, such as cosmic strings [5]. In [4] evidence was presented that a Nielsen-Olesen (Abelian) vortex can ‘thread’ a Schwarzschild black hole. Inclusion of the gravitational back reaction of a single thin vortex led to a metric which is just a conical defect centered on a black hole

([6]). Thus, it was argued that this solution truly is the ‘thin vortex’ limit of a ‘physical’ vortex-black hole configuration. Given these results, one can conclude [4] that the Abelian Higgs vortex is *not* just dressing for the Schwarzschild black hole, but rather that the vortex is truly hair, i.e., a property of the black hole which can be detected by asymptotic observers.

In this paper, we extend the analysis of [4] and allow the black hole to be charged. That is, we consider the problem of an Abelian Higgs vortex in the Reissner-Nordstrom background. In order to ‘turn up’ the electric charge of the hole, we have to allow for the presence of two $U(1)$ gauge fields (one $U(1)$ is where the charge of the hole lives and the other $U(1)$ is the symmetry spontaneously broken in the ground state). We find two striking phenomena:

(i) In the extreme limit (but not near extremality) *all* of the fields associated with the vortex (both the magnetic and scalar degrees of freedom) are expelled from the horizon of the black hole. The magnetic and scalar fields always ‘wrap around’ the horizon in the extremal limit.

(ii) By considering the total energy of the vortex with a black hole inside it, we find an instability as we allow the extreme black hole to become very large compared to the size of the vortex. Specifically, the energy of a vortex which does *not* contain the hole inside it is *much* less than the energy of a vortex which does contain the hole.

In a sense, the behaviour (i) was expected, given that extreme black holes generically display such a ‘Meissner effect’, and so can be thought of as ‘superconductors’ (a deeper analysis of the superconducting properties of extremal black holes and p-branes will be given in [7]). But from (ii) it follows that a very thin vortex will want to ‘slide’ off of the hole. Thus, the vortex cannot in any way be thought of as a ‘property of the black hole which can be measured at infinity’; in other words, an Abelian Higgs vortex is not hair for an extreme black hole.

Our treatment of the black hole/string vortex system involves a clear separation between the degrees of freedom of each of these objects. The action takes the form $S = S_1 + S_2$, where S_1 is an Einstein-Hilbert-Maxwell action for the ‘background’ fields $(g_{\mu\nu}, \mathcal{F}_{\mu\nu})$, and S_2 describes an Abelian Higgs system minimally coupled to

gravity,

$$S_2 = \int d^4x \sqrt{-g} \left(D_\mu \Phi^\dagger D^\mu \Phi - \frac{1}{4e^2} F^2 - \frac{\lambda}{4} (\Phi^\dagger \Phi - \eta^2)^2 \right). \quad (0.1)$$

The degrees of freedom in S_2 are treated as ‘test fields’. They are the complex Higgs field, Φ , and a $U(1)$ gauge field with strength, $F_{\mu\nu}$, and potential A_μ . The Higgs scalar and the gauge field are coupled through the gauge covariant derivative $D_\mu = \nabla_\mu + iA_\mu$, where ∇_μ is the spacetime covariant derivative. We choose metric signature $(+---)$. It is also convenient to define the Bogomolnyi parameter $\beta = \lambda/2e^2 = m_{\text{Higgs}}^2/m_{\text{vector}}^2$. Notice that we have two different gauge fields: F , which couples to the Higgs field and is therefore subject to spontaneous symmetry breaking, and $\mathcal{F}$, which remains massless.

A vortex is present when the phase of $\Phi(x)$ is a non-single valued quantity. To better describe this, define the real fields X , P_μ , χ , by $\Phi = \eta X e^{i\chi}$ and $A_\mu = P_\mu - \nabla_\mu \chi$. The vortex is then characterized by $\oint d\chi = 2\pi N$, the integer N being called the winding number.

We will analyze the equations of the vortex in the background of the Reissner-Nordstrom black hole

$$ds^2 = V dt^2 - \frac{d\rho^2}{V} - \rho^2 (d\theta^2 + \sin^2 \theta d\varphi^2), \quad (0.2)$$

$$V = 1 - \frac{2Gm}{\rho} + \frac{q^2}{\rho^2}.$$

We will work in rescaled coordinates and parameters $(r, E, Q) = \eta\sqrt{\lambda}(\rho, Gm, q)$. In these non-dimensional variables the Higgs mass is unity. The Reissner-Nordstrom black hole has inner and outer horizons where $V(r) = 0$. We will only be interested in the outer horizon, which is at radius $r_+ = E + \sqrt{E^2 - Q^2}$. If $r_+ = E = |Q|$, then $V(r)$ has a double zero at r_+ , and the black hole is said to be extremal.

Return now to the equations of the vortex. One can consistently take $X = X(r, \theta)$, $P_\varphi = NP(r, \theta)$, which simplifies the equations of motion to the form

$$-\frac{1}{r^2} \partial_r (r^2 V \partial_r X) - \frac{1}{r^2 \sin \theta} \partial_\theta (\sin \theta \partial_\theta X) + \frac{1}{2} X (X^2 - 1) + \frac{N^2 X P^2}{r^2 \sin^2 \theta} = 0, \quad (0.3)$$

$$\partial_r (V \partial_r P) + \frac{\sin \theta}{r^2} \partial_\theta \left(\frac{\partial_\theta P}{\sin \theta} \right) - \frac{X^2 P}{\beta} = 0. \quad (0.4)$$

When $P = 1$ (a constant) throughout the space we recover a global string in the presence of the charged hole. The equations (0.3), (0.4), are, in general, rather intractable in exact form and we need to resort to approximation methods. An analytical solution of these equations for the case where the black hole is small relative

to the vortex size is constructed in [8]. Here we resort to numerical integration of the equations (0.3) and (0.4) outside and on the black hole horizon.

The abelian Higgs equations in the presence of a background Reissner-Nordstrom metric are elliptic. On the horizon they become parabolic. In order to solve the equations numerically, we use a technique first used by Achúcarro, Gregory and Kuijken [4]. More details can be found in that reference and in [8]. We have pushed this calculation to the limits, making the vortex as small as we could given the computational constraints. What we have found is that the vortex is *always* expelled, no matter how small the magnetic and Higgs flux tubes are taken to be. Here we present a selection of dramatic pictures of the numerical evidence which we have amassed. The general pattern displayed here holds no matter how small you make the flux tubes.

We begin with the expulsion of the P field by the extreme hole. In the diagram below, we have set $E = Q = 10$, with winding number $N = 1$ (the smallest winding possible). The Bogomolnyi parameter β is set equal to unity, so that the magnetic and Higgs flux tubes are the same size:

Figure 1: Expulsion of the P field from the extreme horizon, for the values $E = Q = 10$, $N = 1$ and $\beta = 1$.

Clearly, the P field ‘wraps’ the black hole horizon; furthermore, given the relation between P and $F_{\theta\varphi}$ it is clear that no magnetic flux is crossing the horizon. The extreme hole behaves just like a perfect diamagnet. But can we ‘puncture’ the horizon with flux by making the magnetic flux tube even smaller? The simplest way to make the vector flux tube thinner is by decreasing the value of β . Since β is the ratio of the sizes of the vector and Higgs flux tubes, making β very small corresponds to making the magnetic flux tube very skinny. However, we still find the P contours all wrap around the black hole horizon, indicating that there is never any penetration.

We now turn to the behaviour of the Higgs field X . We have found that the X field is always expelled from

the extreme hole, no matter how small the scalar flux tube is made. Actually, in the figures below what we do is fix the size of the scalar flux tube (by fixing $N = 1$ and $\beta = 0.5$) and we allow the mass of the extreme hole to increase. The plots run from left to right with increasing mass. The graphs are plotted for the values $E = Q = 1, 5, 10$, and 20 .

Figure 2: Expulsion of the Higgs field from the extreme horizon, for the values $E = Q = 1, 5, 10, 20$; $N = 1$ and $\beta = 0.5$.

The X contours all wrap around the black hole horizon, no matter how large the hole is made. The effect is still true for global strings, where the gauge dynamics is absent.

Now consider the stability of the configurations. Is the black hole stable inside the vortex, or will it try to find its way outside the core? The above sequence provides an intuitive answer to this question. When the black hole is much smaller than the vortex, the black hole is just a ‘hole’ where no vortex energy can be stored. Thus, the presence of the hole tends to subtract the total energy of the vortex. On the other hand, when the hole becomes much larger than the vortex, flux stretches to wrap the hole and so we would expect the total energy of the vortex to become very large.

We have computed the total energy $\mathcal{E}_{bh}$ stored in the vortex when it contains a black hole inside it, for different relative sizes of the core and the horizon (note: in all numerical calculations we introduce an obvious cutoff, i.e., we do not integrate over all of spacetime to obtain the energy, rather we integrate out to the boundaries of some large ‘box’). This is to be compared with the energy of the vortex in the absence of the black hole, $\mathcal{E}_0$. It is always the case that there exists a maximum mass E_{max} such that for all black holes of mass $E < E_{max}$, $\mathcal{E}_{bh}(E) < \mathcal{E}_0$; as long as the hole is not too massive, it prefers to sit inside the vortex.

The statements made above are based on the results of our numerical computations of the total energy $\mathcal{E}_{bh}$. In the figure below we have plotted the results of one such computation. Here, we have set $\beta = 0.5$ and $N = 10$. The flat, horizontal line (at 6640) represents $\mathcal{E}_0$ in our units. Clearly, for these values E_{max} is about 15. Furthermore, for black holes of mass greater than E_{max} the

energy of the vortex is diverging. The erratic behaviour of the vortex energy for very small values of the black hole mass is an artifact of the numerical techniques employed in the calculation and should be ignored:

Figure 3: Plot of total vortex field energy as a function of black hole mass.

It is clear that a black hole with mass $E > 15$ is going to find it energetically favourable to slip out of the vortex. Thus, it is not appropriate to think of such a vortex as a ‘property of the black hole’; the identification of the vortex as long hair does not go through in this situation. When the mass of the hole is small you could still try to identify the vortex with hair since at least in that case the configuration is energetically stable. On the other hand, the fact remains that the vortex is completely expelled from the hole, even in the (putatively) stable situation. Thus one would say that the vortex is not *dressing* the black hole. It is not clear to us whether or not one should think of such a ‘thick’ vortex as genuine hair for a small extreme black hole. This is somewhat a reversal of previously studied situations (e.g., the coloured black holes), where the black hole may be dressed but the configuration is unstable.

A natural question is whether or not similar results continue to hold when the hole is *slightly* non-extreme. Our numerical calculations show that, even when the vortex is very thin relative to the radius of the hole, and the charge is very close to extremality, the flux is expelled only in the exact extreme limit (see [8] for more details).

We have provided strong evidence that the fields of a vortex are always expelled from an extreme horizon. Furthermore, a thin enough vortex tends to slip off the black hole. Thus, it appears that an extreme black hole cannot support ‘long’ Abelian Higgs hair. Of course, we have not accounted for the back reaction of the vortex on the geometry. But there is evidence that the expulsion

may hold exactly: there do exist *exact* solutions for black holes in $U(1)^2$ theories where a black hole that is charged to extremality with respect to one of the gauge fields, completely expels the field of a (Melvin) flux tube of the other gauge field [7]. This strongly suggests that, after accounting for backreaction, the flux should be expelled from an extreme black hole that sits inside it, at least when the vortex is thick. Given the evidence provided above, the effect could well persist in the thin vortex limit. In any case, back reaction would have to be small if the energy scale of symmetry breaking is small compared to the black hole mass.

If, as we have argued, vortices fail to penetrate extreme horizons, there are several interesting implications. Consider what happens when a string tries to *end* at a black hole. It has been argued in [4] that there is no global topological obstruction for a topologically stable string to end at a black hole. This argument is still valid for extreme Reissner-Nordstrom black holes. But what we have found seems to strongly suggest that, even if the penetration on only one side of the hole is topologically feasible, there does not exist a solution of the equations of motion that actually penetrates. We have not analyzed the situation where the string is only on one side of the black hole, but our results very strongly hint that there is no way a vortex can penetrate an extreme horizon: the penetration is a *local* issue, unrelated to global topological considerations. If the string cannot pierce the extreme horizon, then there is no way to construct the Wu-Yang type of patch for the string to end at the black hole. It would follow that a topologically stable string *cannot terminate on an extremal horizon*.¹

Now, there have been a number of papers describing the pair creation of black holes with strings ending on them [9]. In order for the Euclidean instanton that mediates the process to be regular, the black holes must have (unconfined) charge, and be either extremal or close to extremality. This forces one to introduce, in addition to the massive gauge field carried by the string, a (massless) $U(1)$ field to which the black hole charge couples. Effectively, one works in a $U(1)^2$ theory of the same kind we have been discussing in this paper. But if, as we have argued, the string can not end at the extreme horizon, the corresponding instanton does not exist. This would imply that a Nielsen-Olesen string could not snap by forming extreme black holes at its ends. Thus, consideration of ‘realistic’ strings seems to impose new selection rules on string snapping, of a sort somewhat different from

those recently discussed in [11]. A more detailed discussion of these results can be found in [8].

¹Fundamental strings, which in many respects can be regarded as infinitely thin global axion strings, do not possess, however, a core of unbroken symmetry which would be expelled. Therefore, they can end on extreme black holes—and more specifically, on D-branes [10].
